Abstract. This paper discusses technology to support the use of UML for representing ontologies and domain knowledge in the Semantic Web. Two mappings have been defined and implemented using XSLT to produce Java classes and an RDF schema from an ontology represented as a UML class diagram and encoded using XML. A Java application can encode domain knowledge as an object diagram realised as a network of instances of the generated classes. Support is provided for marshalling and unmarshalling this object-oriented knowledge to and from an RDF/XML serialisation. The paper also proposes an extension to RDF allowing the identification of property–resource pairs in a model for which ‘closed world’ reasoning cannot be used due to incomplete knowledge.

1 Introduction

The vision of the Semantic Web is to let computer software relieve us of much of the burden of locating resources on the Web that are relevant to our needs and extracting, integrating and indexing the information contained within. To enable this, resources on the Web need to be encoded in, or annotated with, structured machine-readable descriptions of their contents that are expressed using terms or structures that have been explicitly defined in a domain *ontology*.

Currently, there is a lot of research effort underway to develop ontology representation languages compatible with World Wide Web standards, particularly in the Ontology Inference Layer (OIL [1]) and DARPA Agent Markup Language (DAML [2]) projects. Derived from frame-based representation languages from the artificial intelligence knowledge representation community, OIL and DAML schema build on top of RDF Schema by adding modelling constructs from description logic [3]. This style of language has a well understood semantic basis but lacks both a wide user community outside AI research laboratories and a standard graphical presentation—an important consideration for aiding the human comprehension of ontologies.

This paper discusses Semantic Web technology based on an alternative paradigm that also supports the modelling of concepts in a domain (an ontology) and the expression of information in terms of those concepts. This is the paradigm of object-oriented modelling from the software engineering community. In particular, there is an expressive and standardised modelling language, the Unified Modeling Language (UML [4]), which has graphical and XML-based formats, a huge user community, a high level of commercial tool support and an associated highly expressive constraint language. Although developed to support analysis

and design in software engineering, UML is beginning to be used for other modelling problems, one notable example being its adoption by the Meta Data Coalition¹ [5] for representing metadata schemas for enterprise data.

The proposed application of UML to the Semantic Web is based on the following three claims:

- UML class diagrams provide a static modelling capability that is well suited for representing ontologies [6].
- UML object diagrams can be interpreted as declarative representations of knowledge [7].
- If a Semantic Web application is being constructed using object-oriented technology, it may be advantageous to use the same paradigm for modelling ontologies and knowledge.

However, there is one significant current shortcoming of UML: it lacks a formal definition. The semantics of UML are defined by a metamodel, some additional constraints expressed in a semi-formal language (the Object Constraint Language, OCL), and descriptions of the various elements of the language in English. The development of formal semantics for UML is an active area of research as evidenced by a number of recent workshops [8, 9, 10] and the formation of an open-membership international research group to facilitate work in this area [11]. In particular, as UML is a very large language with some redundancy, research is underway to identify a core of UML modelling constructs from which the other language elements can be derived [12, 13]. A formal definition of this core will then indirectly provide semantics for the complete language.

The present author believes that future developments in this area will provide at least a subset of UML with the formal underpinnings required for the unambiguous interpretation of ontologies. For the present, the use of the more basic features of class and object diagrams for representing ontologies and knowledge seems no more prone to misinterpretation than the use of the Resource Description Framework—a language which underlies the Semantic Web but also lacks official formal semantics (although some have been proposed [14]). It is also worth noting that many of the difficulties in providing precise semantics for UML lie with its features for dynamic modelling of systems, rather than the static models used in the present work.

Further discussion of the benefits and limitations of UML for ontology modelling is beyond the scope of this paper which focuses on technology to support the use of object-oriented modelling for the Semantic Web. An overview of this technology is given in Section 2. Section 3 presents an example ontology in UML and gives a brief description of the features of UML used in this example (for a good introduction to a much larger subset of the language see Muller [15]). Section 4 describes the techniques used to generate an RDF schema and a set of Java classes (complete with RDF-based object marshalling support) from a UML ontology. Section 5 proposes an extension to RDF that allows the inclusion in an RDF model of information on how complete that model is for particular property–resource pairs. Some preliminary thoughts on the possibility of performing reasoning with ontologies and knowledge expressed in UML are presented in Section 6. Finally, Section 7 gives an overview of related work.

¹the MDC has since merged with the Object Management Group to work jointly on the OMG's Common Warehouse Metamodel for data warehousing, business intelligence, knowledge management and portal technology metadata.

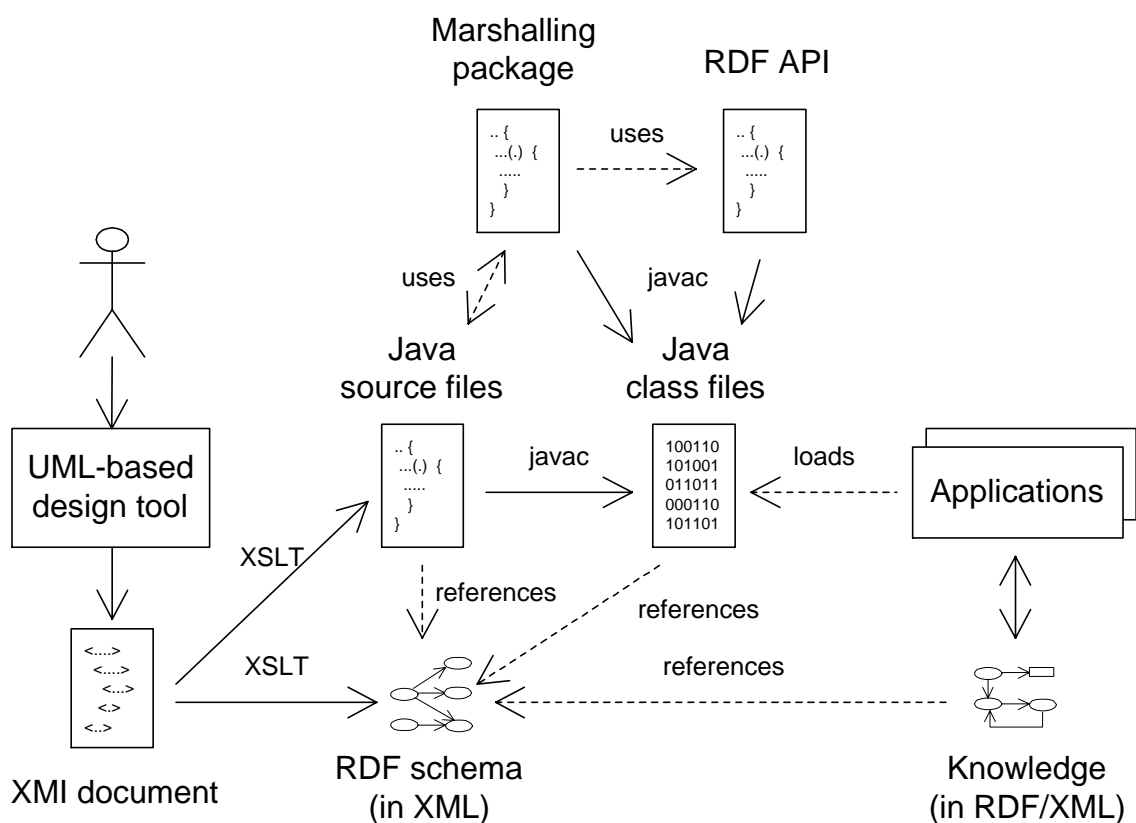

Figure 1: Overview of the implemented technology for object-oriented knowledge representation

2 Required technology for UML and the Semantic Web

To enable the use of UML representations of ontologies and knowledge, standard formats are needed to allow both ontologies and knowledge about domain objects to be published on the Web and transmitted between agents. In addition, there is a need for code libraries to help application writers parse and internalise this serialised information.

This technology already exists for UML class diagrams. The XML Model Interchange language (XMI) defines a standard way to serialise UML models. There are also a number of Java class libraries existing or under development to provide a convenient interface for applications to access this information. However, there is currently no similar technology available to help Java applications construct, serialise and read object-oriented encodings of knowledge that are conceptualised as UML object diagrams. XMI documents can encode the structure of object diagrams, but this is necessarily done in a domain-independent way using separate but cross-referenced XML elements for each object, link, link end and attribute-value binding. What is required is a way to generate from an ontology a domain-specific encoding format for knowledge about objects in that domain, and an application programmer interface (API) to allow convenient creation, import and export of that knowledge.

Figure 1 shows an approach to object-oriented ontological and object-level knowledge representation that has been implemented and is described in this paper. First, a domain expert designs an ontology graphically using a CASE tool supporting the Unified Modeling Language, and then saves it using the standard XML-based format XMI (XML Model Interchange). A pair of XSLT (Extensible Stylesheet Language Transformations) stylesheets then

take the XMI representation of the ontology as input and produce (i) a set of Java classes and interfaces corresponding to those in the ontology, and (ii) a representation of the ontology using RDF (Resource Description Framework) using the modelling concepts defined in RDF Schema. The generated Java classes allow an application to represent knowledge about objects in the domain as in-memory data structures. The generated schema in RDF defines domain-specific concepts that an application can reference when serialising this knowledge using RDF (in its XML encoding). The marshalling and unmarshalling of object networks to and from RDF/XML documents is performed by a pair of Java classes: `MarshalHelper` and `UnmarshalHelper`. These delegate to the generated Java classes decisions about the names and types of fields to be serialised and unserialised, but are then called back to perform the translation to and from RDF, making use of an existing Java RDF application programmer's interface [16].

Note that the generated RDF schema does not contain all the information from the original UML model. If an application needs access to full ontological information, it can use the original XMI document with the help of one of the currently available or forthcoming Java APIs supporting the processing of UML models. The purpose of the RDF schema is to define RDF resources corresponding to all the classes, interfaces, attributes and associations in the ontology in order to support RDF serialisation of instance information. For the sake of human readers, the schema records additional information such as subclass relationships and the domains and ranges of properties corresponding to attributes and associations. However, this information is not required for processing RDF-encoded instance information because each generated Java class contains specialised methods `marshalFields` and `unmarshalFields` containing hard-coded knowledge about the names and types of the class's fields. This is a design decision intended to avoid potentially expensive analysis of the schema during marshalling and unmarshalling. This it should be possible to use this serialisation mechanism in situations where optimised serialisation is important, such as in agent messaging systems.

3 An example domain

This section presents an example ontology modelled as a UML class diagram and some knowledge encoded as an object diagram. The ontology defines a subset of the concepts included in the CIA World Factbook and is adapted from an OIL representation of a similar subset [17].

3.1 An ontology in UML

Figure 2 presents the CIA World Factbook ontology represented as a UML class diagram. The version shown here is not a direct translation from OIL: there is an additional class `AdministrativeDivision`, UML association classes are used where appropriate, and instead of defining the classes `City` and `Country` as specialised types of `Region` (GeographicalLocation in the OIL original), the ontology represents these as optional roles that a region may have.

The boxes in the diagram represent classes, and contain their names and (where applicable) their attributes. The lines between classes depict association relationships between

Figure 2: A UML ontology for a subset of the CIA World Factbook

classes. A class A has an association with another class B if an object of class A needs to maintain a reference to an object of class B. An association may be bidirectional, or (if a single arrowhead is present) unidirectional. A ‘multiplicity’ expression at the end of an association specifies how many objects of that class may take part in that relationship with a single object of the class at the other end of the association. This may be expressed as a range of values, with ‘*’ indicating no upper limit. Association ends may be optionally named. In the absence of a name, the name of the adjacent class, with the initial letter in lower case, is used as a default name. Associations can be explicitly represented as classes by attaching a class box to an association (see LandBoundary and AreaComparison in the figure). This is necessary when additional attributes or further associations are required to clarify the relationship between two classes.

The dog-eared rectangle in the lower left corner of the figure contains a constraint in the Object Constraint Language (OCL). This language provides a way to constrain the possible instances of a model in ways that cannot be expressed using UML’s structural modelling elements alone. The constraint shown here states that i) a country’s capital is a city in that country, and ii) if a country *c* has another as a neighbour, then that neighbouring country has *c* as a neighbour. Finally, the keyword “datatype” appearing in guillemets above the class Real indicates that this is a pre-existing built-in datatype. OCL defines a minimal set of primitive datatypes and it is currently assumed that the ontology designer has used these primitive types.

Note that UML includes notation for class generalisation/specialisation relationships, although this is not required for the example presented in this paper.

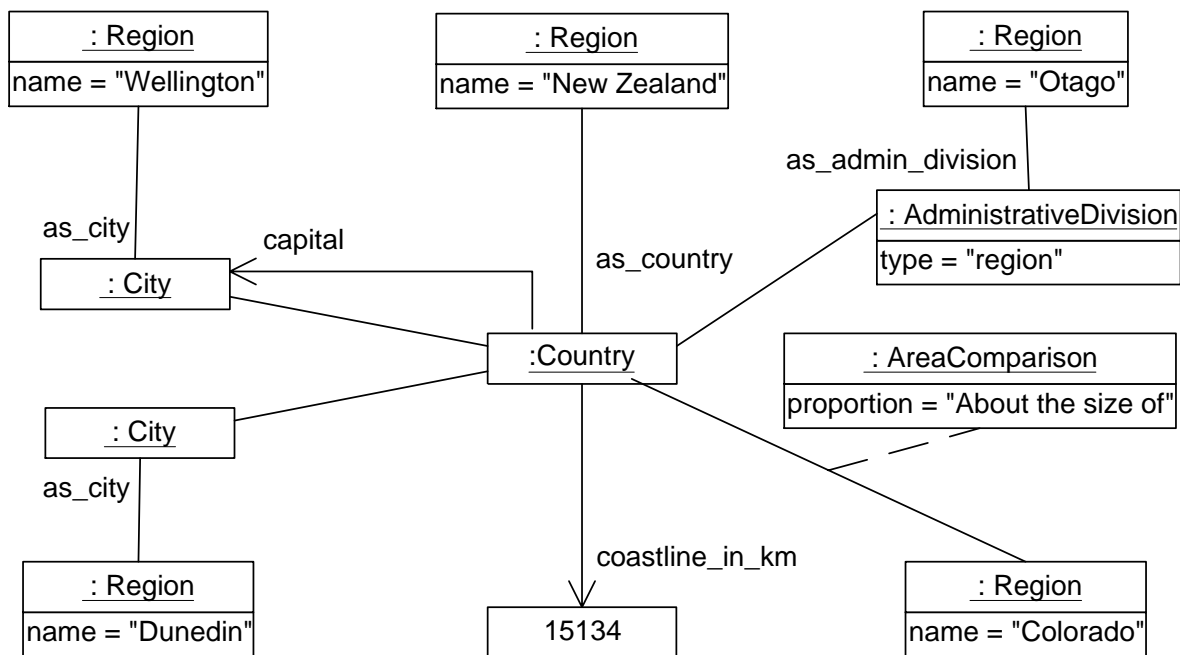

Figure 3: Information about New Zealand as a UML object diagram

3.2 Knowledge as an object diagram

Figure 3 presents some knowledge about New Zealand from the CIA World Factbook, expressed as an object diagram. For brevity, this diagram omits most of New Zealand's cities and administrative divisions, and provides no information about the region named Colorado, to which New Zealand is compared in terms of area.

In object diagrams, rectangles denote objects, specifying their class (after an optional name and a colon) and the object's attribute values. The lines between objects show 'links': instances of associations between classes.

4 From UML to RDF and Java

The previous section presented some knowledge expressed as a UML object diagram. This is an abstract representation of that knowledge. To enable this style of knowledge representation to be used for Semantic Web applications it is necessary to define an API to allow creation of the knowledge in this form and a serialisation format to allow Web publication and transmission of the knowledge. These can be generated automatically from an XML encoding of the Word Factbook using the XSLT stylesheets that have been developed. One stylesheet produces an RDF schema corresponding to the ontology and the other produces a corresponding set of Java classes and interfaces.

XSLT is a language for transforming XML documents into other documents. An XSLT stylesheet is comprised of a set of templates that match nodes in the input document (represented internally as a tree) and transform them (possibly via the application of other templates) to produce an output tree. The output tree can then be output as text or as an HTML or XML document.

The main issue common to both mappings is the problem of translating from UML

classes, which may have different types of features such as attributes, associations and association classes, to a model where classes only have fields or (in RDF) properties. It was also necessary to generate default names for fields where association ends are not named in the UML model. The OCL conventions for writing navigation paths through object structures were used to resolve these issues. Also, attributes and association ends with a multiplicity upper limit greater than one are represented as set-valued fields (bags in RDF Schema) or, in the case of association ends with a UML “ordered” constraint, list-valued fields (sequences in RDF Schema). Further details about the mappings have been discussed elsewhere [18] and are beyond the scope of this paper.

4.1 The generated RDF schema

The Resource Description Framework (RDF) is a simple resource–property–value model designed for expressing metadata about resources on the Web. RDF has a graphical syntax as well as an XML-based serialisation syntax. For readability, examples in this paper are presented in the graphical syntax, although in practice they are generated in the XML format.

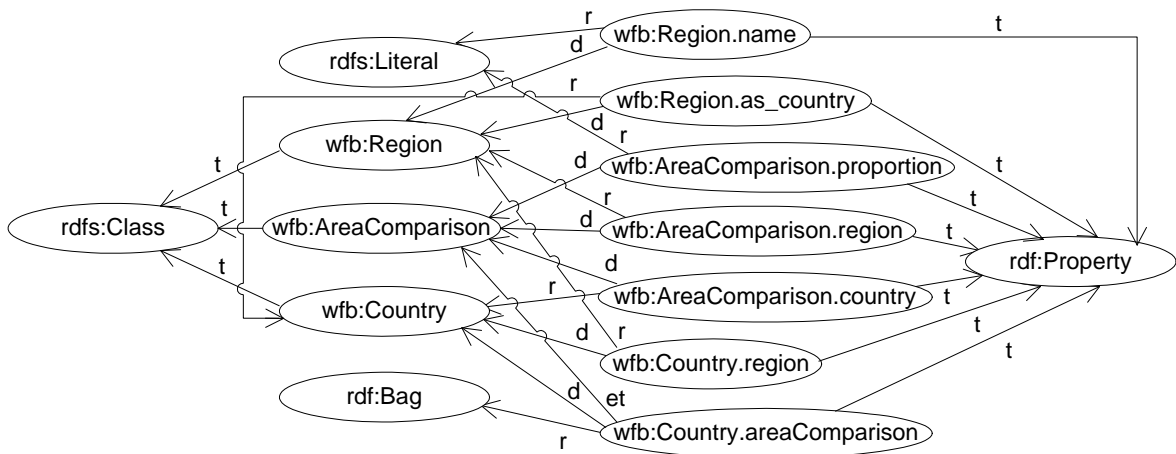

RDF Schema is a set of predefined resources (entities with uniform resource identifiers) and relationships between them that define a simple meta-model including concepts of classes, properties, subclass and subproperty relationships, a primitive type `Literal`, bag and sequence types, and domain and range constraints on properties. Domain schemas (i.e. ontologies) can then be expressed as sets of RDF triples using the (meta)classes and properties defined in RDF Schema. Schemas defined using RDF Schema are commonly called RDF schemas (small ‘s’).

The main issue in generating an RDF schema that corresponds to an object-oriented model is that RDF properties are first-class objects and are not defined within the context of a particular class. This can lead to conflicting range declarations if the same property (e.g. `head`) is used to represent a field in two different classes (e.g. `Brew` and `Department`). The solution chosen was to prefix each property name representing a field with the name of the class. This has the disadvantage that in the presence of inheritance a class’s fields may be represented by properties with different prefixes: some specifying the class itself and some naming a parent class. This might be confusing for a human reader but is not a problem for the current purpose: to specify a machine-readable format for object-oriented knowledge interchange.

Figure 4 presents a subset of the generated RDF schema corresponding to the UML model presented in Figure 2. Only the classes `Country` and `Region` and the relationships between them are included here.

In the standard RDF graphical notation used in the figure, an ellipse represents a resource with its *qualified name* shown inside as a namespace prefix followed by a local name. A namespace prefix abbreviates a Uniform Resource Identifier (URI) associated with a particular namespace, and the URI for the resource can be constructed by appending the local name to the namespace URI. A property is represented by an arc, with the qualified name for the property written beside the arc (in this case the arcs are given labels with the corresponding URIs shown in the table).

Figure 4 includes one property that is not part of RDF Schema. There is no mechanism in RDF Schema to parameterise a collection type (such as `rdf:Bag`) by the class of elements it may contain. Therefore, the non-standard property `rdfsx:collectionElementType` was introduced to represent this information (this is abbreviated in the figure by the arc label

Property labels	Name space abbreviations
t = rdfs:type	rdf = http://www.w3.org/1999/02/22-rdf-syntax-ns#

et = rdfsx:collectionElementType	wfb = any new namespace chosen for this schema

Figure 4: Part of the World Factbook schema in RDF

et). The definition of this property is shown in Figure 5. The object serialisation mechanism described in this paper does not require this information but it is useful to people reading the schema.

The schema in Figure 4 completely defines the encoding of instance data in RDF. Figure 6 shows how an object diagram is encoded in RDF with reference to the schema. This corresponds to the central Region and Country objects from Figure 3 together with the AreaComparison link to the Colorado Region object. The five resources outlined in bold are the ones being defined. There are two resources of type wfb:Region, one of type wfb:Country, one of type rdfs:Bag (representing the set of the country's area comparisons) and one element in the bag, an instance of the area comparison association class (which is represented in RDF as the type wfb:AreaComparison). Depending on the needs of the

application, defined objects might be assigned URIs or represented as anonymous resources. In this case, they are anonymous—the labels x and y are included to allow reference to these resources later in this paper. The rectangles represent RDF literals.

Note that while this graphical notation for RDF looks complicated, its encoding in XML only requires five XML elements to represent the information, as shown in the appendix.

4.2 The generated Java classes and marshalling framework

The generated RDF schema described in the previous section defines a domain-specific serialisation format for object-oriented representation of knowledge about the domain. To facilitate the processing of knowledge communicated in this form, a set of Java classes can also be generated from the ontology using XSLT. These allow Java applications to instantiate instances of the domain concepts. In addition, the generated classes, along with some additional utility classes, allow these in-memory structures to be marshalled and unmarshalled to and from the RDF serialisation format defined by the generated RDF schema. The aim of the marshalling code is to allow a Java application to maintain an internal representation of object-oriented knowledge and to easily read and write parts of this knowledge to and from a format suitable for transmission or publication on the Web.

Figure 7 presents a class diagram outlining the structure of the generated Java classes and the marshalling framework. The class `MarshalHelper` is part of a support package used by the generated classes. A static method `marshalObjects` provides the entry point for an application to marshal a network of objects. A similar class `UnmarshalHelper` is

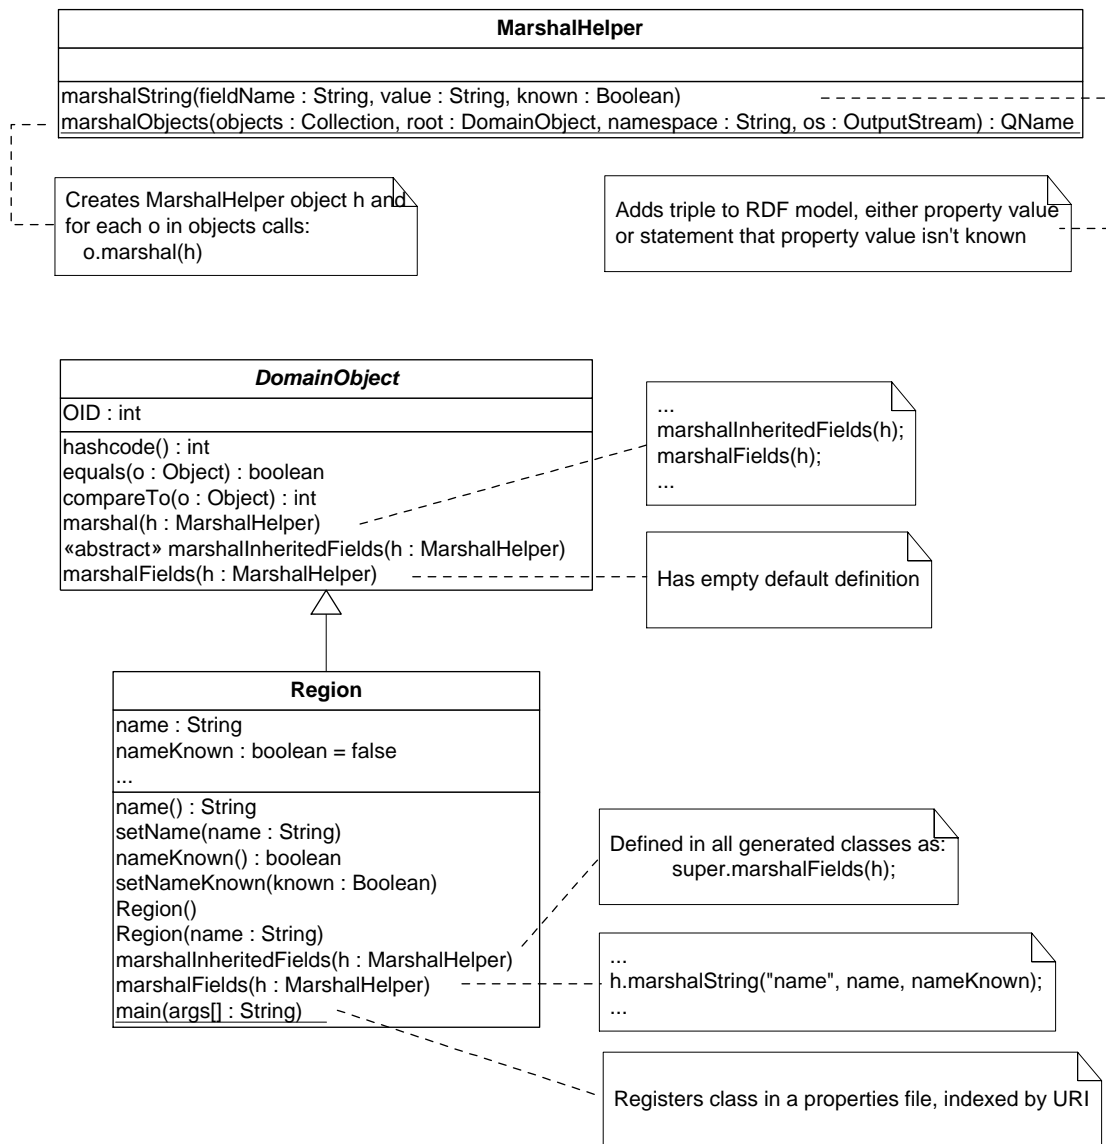

Figure 7: The structure of the generated classes and the marshalling methods

also provided, but is not discussed here. The class `DomainObject` is an abstract base class that all generated classes specialise (the specialisation relationship is represented by a closed arrow pointing to the more general class). The class `Region` is shown as an example of a generated class.

This diagram does not show all the fields and methods. In particular, the class `Region` also contains fields and methods related to the association ends `as_city`, `as_country` and `as_admin_division` from the ontology shown in Figure 2. There are some fields and methods depicted that are related to whether or not a field value is “known”. This is discussed in Section 5.

There is a significant difference between knowledge represented propositionally and knowledge represented in the form of an object diagram. Propositions are self-contained statements of knowledge whereas object diagrams are networks of objects. When serialising knowledge, an application may only wish to include some of the information it knows about a domain.

```

// Build object diagram
Region rNZ = new Region("New Zealand");
Country cNZ = new Country();
AreaComparison ac = new AreaComparison();
ac.setCountry(cNZ);
ac.setRegion(rNZ);
ac.setProportion("About the size of");
Set comparisons = new HashSet();
comparisons.add(ac);
Region rColorado = new Region("Colorado");
rNZ.setAs_country(cNZ);
cNZ.setRegion(rNZ);
cNZ.setAreaComparisonSet(comparisons);
// Now marshal it
Set toMarshal = new HashSet();
toMarshal.add(rNZ); toMarshal.add(cNZ);
toMarshal.add(ac); toMarshal.add(rColorado);
try {
    QName rootQName =
        MarshalHelper.marshalObjects(
            toMarshal, rNZ, "http://nzdis.otago.ac.nz/nzdata1#",
            new FileOutputStream("nz.xml"));
}
catch (MarshallingException e) { ... }

```

Figure 8: Sample Java code to create and marshal an object diagram

For example, Figure 6 compares New Zealand’s area to that of Colorado, but doesn’t provide the information that Colorado is an administrative division of the United States. To allow this selectivity, the `marshalObjects` method takes a collection of objects as an argument. Links to any objects outside this collection will not be serialised. To allow a particular entry point into the knowledge structure to be identified, a root object is specified and the method returns the qualified name of the RDF resource in the serialised model that represents that object. A namespace for the serialised information is also provided.

Figure 8 shows the Java code that would produce the RDF serialisation in Figure 6.

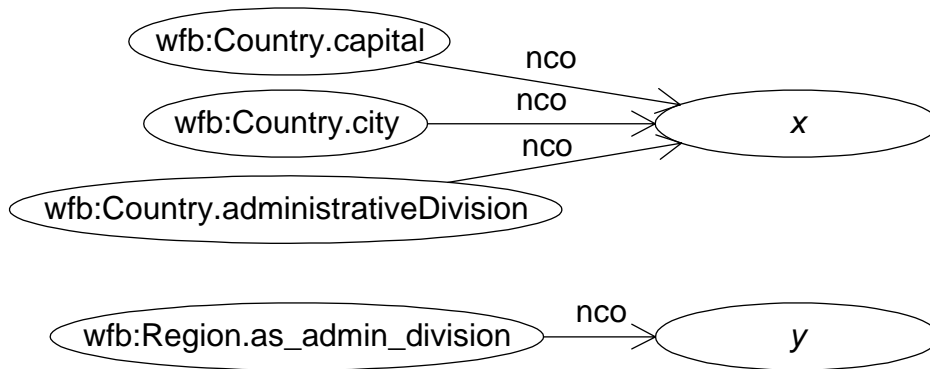

5 Modelling incomplete knowledge

Because object diagrams are inter-linked networks of objects rather than sets of discrete facts, and because classes may have attributes or associations that are optional (i.e. have a multiplicity lower bound of zero), it is important to be able to distinguish between a statement that there are no values for a given property and the omission or lack of knowledge about a given property. In other words, the recipient of object-oriented information needs a way of knowing for which objects and which properties a closed world assumption can safely be made. This is achieved by including extra boolean fields in the generated Java classes that record for each regular field whether or not its value is ‘known’ or, for set- or list-valued fields, ‘closed’—meaning that the contents of the set or list provide complete knowledge of that field. Setting the value of a single-valued field sets its ‘known’ field to true and all fields also have a method

Property labels	Name space abbreviations
t = rdf:type	rdf = http://www.w3.org/1999/02/22-rdf-syntax-ns#
d = rdfs:domain	rdfs = http://www.w3.org/2000/01/rdf-schema#
r = rdfs:range	rdfx = http://nzdis.otago.ac.nz/0_1/rdf-x#

Figure 9: Schema for the notClosedOn property

Property labels	Name space abbreviations
nco = rdfx:notClosedOn	rdfx = http://nzdis.otago.ac.nz/0_1/rdf-x#
	wfb = namespace chosen for the World Factbook schema

Figure 10: Meta-knowledge about incomplete information

allowing the programmer to explicitly specify the status of the field.

When unmarshalling an object diagram from the RDF encoding it is assumed that complete information about all properties is included unless otherwise specified (although the opposite could equally well be implemented as the default assumption). Incomplete information is indicated using a non-standard RDF property `notClosedOn` that associates a property with a resource, meaning that complete information is not provided for that property applied to that resource. Figure 9 shows the declaration of the `notClosedOn` property.

Figure 10 presents an example of this property applied to the encoding of knowledge about New Zealand that was shown in Figure 6. When combined with the RDF-encoded information in Figure 6, this specifies that the RDF model does not contain complete (or possibly any) information about the capital, cities and administrative divisions of the country represented by the resource labelled *x*. Also, there is possibly missing information about the administrative division property of the region represented by the resource labelled *y*.

In order to have this meta-level information added to the RDF serialisation, the Java code shown in Figure 8 must have the following lines added before the call to `marshalObjects`:

```
cNZ.setCapitalKnown(false);
cNZ.setCitySetClosed(false);
cNZ.setAdministrativeDivisionSetKnown(false);
rNZ.setAs_admin_divisionKnown(false);
```

Similar mechanisms for handling incomplete knowledge have been used in knowledge representation systems LOOM [19] (which includes `:closed-world` and `:open-world` relation properties) and CLASSIC [20] (which allows roles to be declared to be ‘closed’). This notion has also been formalised in description logic by the use of epistemic operators that modify roles, and in AI planning by the use of “local closed world” formulae [21]. The `notClosedOn` property used in this work should also include a reference to the current RDF model, but this is not currently possible as RDF does not provide a way to declare that a set of statements collectively constitute a model with a given URI.

6 Reasoning with OCL

The Semantic Web, as envisioned by Tim Berners-Lee [22], includes a logical layer which allows “the deduction of one type of document from a document of another type; the checking of a document against a set of rules of self-consistency; and the resolution of a query by conversion from terms unknown into terms known”. One of the biggest challenges for the Semantic Web community is to find interoperable ways of incorporating inference rules into ontologies. There is much research to be done in this area. For example, although the XML DTD for OIL 1.0 defines a `rule-base` element, its content is unconstrained text and no semantic connection is made between this rule base and the rest of the language. The RDF schemas defining later versions of OIL and DAML do not currently contain any way of representing rules, although it is a goal of the DAML project to produce an enhanced language, DAML-L, with support for rules.

It is therefore an important question to evaluate how well UML fares in this regard. In fact, UML includes a powerful mechanism for expressing inference rules: the Object Constraint Language. OCL has been claimed to be “essentially a variant of [first order predicate logic] tuned for writing constraints on object structures” [23]. This claim is true from a syntactic viewpoint: OCL is sufficiently expressive to represent any first-order inference rules that an ontology designer may wish to specify (although this expressiveness also means that reasoning about unconstrained OCL expressions is likely to be undecidable in general). From a semantic viewpoint, the above claim cannot be verified as OCL currently lacks a formal specification. However, this shortcoming has been recognised in the UML 2.0 OCL RFP [24] and at least one proposal for formal semantics for OCL has already been made [25].

The object-oriented syntax of OCL is also unlike any commonly used logical language, and attempting to write rules in OCL can be frustrating for the inexperienced. A constraint can often be expressed in several different ways and the resulting expression can look quite unlike its counterpart in first-order logic. Consider the constraint in Figure 2. The second conjunct specifies that the neighbourhood relationship between countries is reflexive. The form of this constraint might be immediately recognised as a standard pattern by an OCL expert but it is not obvious to the uninitiated.

To enable tractable reasoning about ontologies in UML, and to avoid the awkward syntax of OCL, it would be useful to define a macro language on top of OCL comprising predicates such as `reflexive(path-expression)` which are defined in terms of OCL. The set

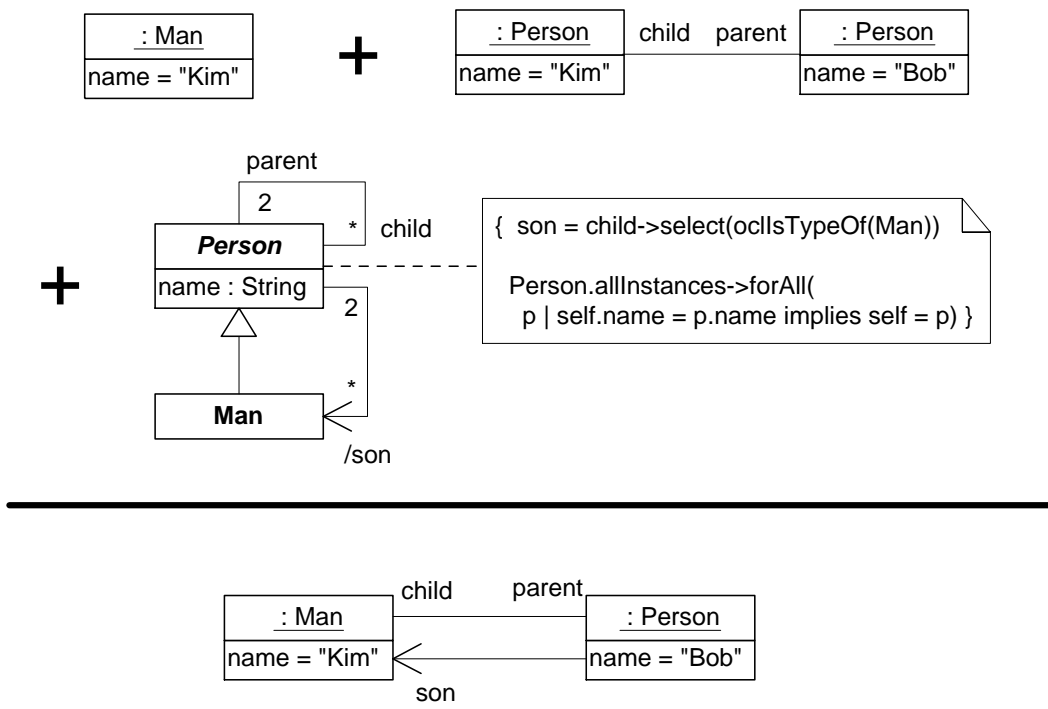

Figure 11: An example of inference over knowledge in UML

of macros could be chosen to ensure that reasoning over these expressions is tractable. This would also help to allow the translation of rules between UML-based and other representations of an ontology. This is a subject for future research.

Recent research has also shown how inference rules in UML can be expressed as graph transformations on the UML metamodel [26, 13]. To give a taste of what inference with UML might look like, Figure 11 shows how new knowledge in the form of an object diagram can be generated by combining existing knowledge and information about the ontology. In this example, one agent has communicated to another that there is an object of class *Man* with “Kim” as the value of its name attribute. The other agent knows that there is a *Person* object with name Kim and that this object is the child of a *Person* object with name Bob. The ontology for this domain states that *Man* is a specialisation of *Person*, and includes two OCL constraints: one defining the derived role (indicated by ‘/’) *son* (a son is a child that is a man), and the other stating (rather unrealistically) that the name attribute uniquely identifies objects of class *Person*. Over several steps of inference the agent can conclude that the two objects with name Kim are the same and therefore Kim is a male child, i.e. a son. Implementing this style of deduction in UML is a subject for future research.

7 Related Work

A number of other projects have investigated the serialisation of instances of ontological models.

Skogan [27] defined a mechanism for generating an XML document type definition (DTD) from a UML class diagram and implemented this as a script for the UML-based modelling

tool Rational Rose. This is being used for the interchange of geographical information. The mapping is only defined on a subset of UML and many useful features of class diagrams, including generalisation relationships, are not supported.

Work has also been done on producing DTDs [28] and XML schemas [17] from models expressed in ontology modelling languages (Frame Logic and OIL respectively). The latter work reported that the XML Schema notion of type inheritance does not correspond well to inheritance in object-oriented models, which was a factor in the choice of RDF as a serialisation format in the research described here.

Since its initial proposal, OIL has been redesigned as an extension of RDFS [29]. This means that an ontology in OIL is also an RDF schema and therefore knowledge about resources in a domain modelled by an OIL ontology can easily be expressed using RDF.

The UML-based Ontology Toolset (UBOT) project at Lockheed Martin is working on tools to map between UML and DAML representations of ontologies [30]. This project has a different focus from the work described in this paper. Rather than using the existing features of UML to describe ontologies, the language is being extended with a set of UML ‘stereotypes’ (specialisations of UML modelling constructs) that correspond to classes and properties in the RDF schema for DAML. A proposal has also been made for an extension to the UML metamodel that would allow global properties in DAML ontologies to be modelled as aggregations of UML association ends (which are local to classes) [31].

The Web site <http://www.interdataworking.com> provides a number of ‘gateways’ that can be used to convert between different data formats. One particular ‘gateway stack’ can be used to produce an RDF schema from an XMI document, although no information is given about the mapping and how much of UML is supported. The resulting schema is defined using a mixture of properties and (meta)classes from RDF Schema (such as `rdfs:subClassOf`) and from Sergey Melnik’s RDF representation of the UML metamodel [32]. The schema defines properties and classes that can be referenced when encoding object information in RDF, and could itself be used as an alternative to an XMI encoding for publishing and serialising an ontology modelled using UML. However, as XMI is an Object Management Group standard for model interchange, it is being supported by an increasing number of tools and APIs and there seem to be few advantages in using a different format for encoding UML models. If it is required to annotate an ontology with additional information that is not part of the XMI format (one of Melnik’s desiderata) this could be achieved using external annotations and XLink [33].

Xpetal [34] is a tool that converts models in the ‘petal’ output format of the UML-based modelling tool Rational Rose to an RDF representation. No details are provided about the mapping from UML to RDFS and which UML features are supported.

8 Conclusion

This paper has described technology that facilitates the application of object-oriented modelling, and the Unified Modeling Language in particular, to the Semantic Web. From an ontology specified in UML, a corresponding RDF schema and a set of Java classes can be automatically generated to facilitate the use of object diagrams as internal knowledge representation structures and the import and export of these as RDF documents. A mechanism was also introduced for indicating when an object diagram has missing or incomplete knowledge.

Important areas for future work are the identification of tractable subsets of OCL for

encoding inference rules and the definition of mappings between object-oriented representations of ontologies and knowledge and more traditional description logic-based formalisms. This would allow applications to choose the style of modelling most suitable for their needs while retaining interoperability with other subsets of the Semantic Web.

The software described in this paper is publicly available at <http://nzdis.otago.ac.nz/projects> under the name “uml-data-binding”.

Appendix

The following is an XML serialisation of the RDF model representing information about New Zealand that was shown in Figure 6.

```
<rdf:RDF
  xmlns:wfb="http://nzdis.otago.ac.nz/0_1/world-fact-book#"
  xmlns:rdf="http://www.w3.org/1999/02/22-rdf-syntax-ns#">

  <wfb:Region rdf:ID="region1">
    <wfb:Region.name>New Zealand</wfb:Region.name>
    <wfb:Region.as_country rdf:resource="#country1"/>
  </wfb:Region>

  <wfb:Country rdf:ID="country1">
    <wfb:Country.region rdf:resource="#region1"/>
    <wfb:Country.areaComparison rdf:resource="#bag1"/>
  </wfb:Country>

  <rdf:Bag rdf:ID="bag1">
    <rdf:li rdf:resource="#comparison1"/>
  </rdf:Bag>

  <wfb:AreaComparison rdf:ID="comparison1">
    <wfb:AreaComparison.country rdf:resource="#country1"/>
    <wfb:AreaComparison.region rdf:resource="#region2"/>
    <wfb:AreaComparison.proportion>About the size of
  </wfb:AreaComparison.proportion>
  </wfb:AreaComparison>

  <wfb:Region rdf:ID="region2">
    <wfb:Region.name>Colorado</wfb:Region.name>
  </wfb:Region>

</rdf:RDF>
```
